Abstract

We consider bosonic noncritical strings as QCD strings and we present a basic strategy to construct them in the context of Liouville theory. We show that Dirichlet boundary conditions play important roles in generalized Liouville theory. Specifically, they are used to stabilize the classical configuration of strings and also utilized to treat tachyon condensation in our model. We point out that Dirichlet boundary conditions for the Liouville mode maintains Weyl invariance, if an appropriate condition is satisfied, in the background with a (non-linear) dilaton.

1 Introduction

Gauge theories and string theories are very important fields of modern theoretical physics. Construction of a non-perturbative formulation of string theories is one of the main subjects which has not yet been completely understood. Although non-perturbative formulations of gauge theories were constructed as lattice gauge theories, we are still interested in analytical studies on non-perturbative effects of gauge theories. The relation between gauge theories and string theories has been studied for a long time, and both theories have developed while affecting each other deeply. Thus, studies on the connection between them seems to be important and is expected to be fruitful. With this in mind, we consider QCD strings in this article, from the viewpoint of Liouville theory.

Investigation of non-perturbative effects of QCD (for example, confinement of quarks) has been one of the motivations for string theories. In the context of QCD strings, confinement of quarks is explained in terms of a linear potential produced by the “string” stretched between quark and antiquark. There are many reasons why we consider such a string theory, although this naive explanation has not been completed nor proved to this time.²

In the strong coupling expansion of lattice gauge theories, the quark-antiquark potential is given by the expectation value of the Wilson loop, each term of which corresponds to different configuration of the lattice surfaces. This reminds us of the sum of the “world-sheet surfaces” of an open string whose boundary is the Wilson loop. We can find another description of gauge theories in terms of strings in the large- N limit. In large- N gauge theories, Feynman diagrams are classified by the “Euler number,” and the physical observables are expressed as a series with respect to the “topology” of the graph. The dominant terms correspond to planar diagrams. This also reminds us of a “world-sheet” description. Furthermore, in the description of the dual Meissner effect, the fluxes of color electric charge are collimated, and form a “string” between quarks. We also find similar correspondence between gauge theories and string theories in the contexts of D-branes and AdS/CFT.³

In consideration of the above discussion, we study QCD strings with the following assumptions.

(1) We assume that the color charge is attached to the ends of open strings, and we regard the world-sheet boundaries as Wilson loops.

(2) The Wilson loops are not dynamical, since we attempt to describe pure YM theories

²For a review of these topics, see Ref. [1].

³We have found other connections between gauge theories and strings [1].

in which quarks are not dynamical.

(3) We assume that the strings are bosonic and exist in four-dimensional spacetime, because our purpose is to describe four-dimensional (large- N) non-SUSY gauge theories.

2 Review of Liouville theory

It is most natural to assume that QCD strings are bosonic and four-dimensional objects. Therefore, we must find some nontrivial way to construct a consistent noncritical string theory.

Quantization of noncritical strings has been considered in Liouville theories [2, 3]. In particular, strings for $d \leq 1$ have been consistently quantized using DDK theory presented by Distler and Kawai [4] and David [5]. (Here d denotes the spacetime dimension in which strings exist.) For this reason, we first review the work on the DDK theory.⁴

2.1 DDK theory without boundaries

Let us start with a d -dimensional ($d \neq 26$) bosonic string without boundaries for simplicity. We use the Euclidean signature both for the world-sheet metric and for the spacetime metric. The Polyakov action is

$$S_M = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{g} (g^{ab} \partial_a X^\mu \partial_b X_\mu), \quad (2.1)$$

where μ runs from 1 to d . The partition function with respect to this action is diffeomorphism invariant, and we can fix the world-sheet metric as

$$g_{ab} = \hat{g}_{ab} e^{\phi(\xi)}. \quad (2.2)$$

However, the Weyl invariance of the partition function is broken for $d \neq 26$ at the quantum level, and the freedom of the Weyl transformation is no longer a gauge freedom. Therefore, we have to perform the path integral with respect to ϕ rigorously. However, the measure $[d\phi]_g$ of the path integral with respect to ϕ is given by the norm

$$\|\delta\phi\|_g = \int d^2\xi \sqrt{g} (\delta\phi)^2 = \int d^2\xi \sqrt{\hat{g}} e^{\phi(\xi)} (\delta\phi)^2, \quad (2.3)$$

which depends on ϕ itself in a complicated manner. Thus, to perform the path integral with this measure is difficult and seems to be almost impossible.

⁴For a review of DDK, see Ref. [6].

In Liouville theory based on the DDK argument, the measure of the path integral is redefined with respect to some fixed world-sheet metric $\hat{g}_{ab}$ to avoid the above described difficulty. Namely, we use the measure $[d\phi]_{\hat{g}}$ given by the norm

$$\|\delta\phi\|_{\hat{g}} = \int d^2\xi \sqrt{\hat{g}} (\delta\phi)^2, \quad (2.4)$$

which does not depend on ϕ . With this redefinition, we have to use a Jacobian J to maintain consistency:

$$[dX]_g [db]_g [dc]_g [d\phi]_g = [dX]_{\hat{g}} [db]_{\hat{g}} [dc]_{\hat{g}} [d\phi]_{\hat{g}} J, \quad (2.5)$$

$$J = e^{-S_L}, \quad (2.6)$$

where b and c are the ghost fields. We have the relations [2]

$$[dX]_g [db]_g [dc]_g = [dX]_{\hat{g}} [db]_{\hat{g}} [dc]_{\hat{g}} e^{-S_{\text{Jac}}} \quad (2.7)$$

$$S_{\text{Jac}} = \frac{1}{2} \frac{26-d}{48\pi} \int d^2\xi \sqrt{\hat{g}} \{ \hat{g}^{ab} \partial_a \phi \partial_b \phi + 2\hat{R}\phi \}, \quad (2.8)$$

where $\hat{R}$ is the world-sheet scalar curvature with respect to the metric $\hat{g}_{ab}$. (Note that (2.7) does not contain $[d\phi]$, while (2.5) *does* contain $[d\phi]$.) Therefore, the Jacobian J can be naturally assumed to be

$$S_L = u \int d^2\xi \sqrt{\hat{g}} \{ \hat{g}^{ab} \partial_a \phi \partial_b \phi + q\hat{R}\phi \}, \quad (2.9)$$

where u and q are some constants.

Then, the total action, including the Jacobian term, is

$$\begin{aligned} S &= S_M + S_L + S_{\text{ghost}} \\ &= \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{\hat{g}} \{ \hat{g}^{ab} \partial_a \varphi \partial_b \varphi + \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu + \alpha' Q \hat{R} \varphi \} + S_{\text{ghost}}, \end{aligned} \quad (2.10)$$

where we have redefined the factor q and the field ϕ as

$$Q = \sqrt{\frac{4\pi u}{\alpha'}} q, \quad (2.11)$$

$$\varphi(\xi) = \sqrt{4\pi\alpha' u} \phi(\xi) = \frac{q}{Q\alpha'} \phi(\xi). \quad (2.12)$$

In the action (2.10), the field φ has a kinetic term and can be regarded as a new “coordinate” of the target space⁵; we obtain one more spacetime dimension and a linear dilaton term through the process of quantization. The world-sheet metric g_{ab} has been replaced with $\hat{g}_{ab}$ in the process.

Let us consider the partition function Z with respect to the action (2.10),

$$Z = \int [d\varphi][dX] e^{-S}, \quad (2.13)$$

where $[d\varphi]$ and $[dX]$ stand for $[d\varphi]_{\hat{g}}$ and $[dX]_{\hat{g}}$. (We omit $\hat{g}$ from expressions of the measure in the following.) Here $[dX]$ represents the measure with respect to the matter and the ghost. It also represents the measure for the modular integration if $N_g > 0$, where N_g is the number of the genus of the world-sheet.

We note that the partition function does not change under the simultaneous transformations that keep $g_{ab} = \hat{g}_{ab} e^{\frac{Q\alpha'}{q}\varphi}$ invariant,

$$\hat{g}_{ab} \mapsto \hat{g}_{ab} e^{\delta(\xi)}, \quad (2.14)$$

$$\varphi(\xi) \mapsto \varphi(\xi)' = \varphi(\xi) - \frac{Q\alpha'}{q} \delta(\xi), \quad (2.15)$$

if the boundary condition of the integration in (2.13) allows the shift of φ given by (2.15). This is because the action in the initial formulation (2.1) depends only on g_{ab} and X^μ , which do not change under the above transformations. Thus,

$$Z = \int [d\varphi][dX] e^{-S[\hat{g}, X, \varphi]} = \int [d\varphi'] [dX] e^{-S[\hat{g} e^{\delta(\xi)}, X, \varphi']}. \quad (2.16)$$

After rewriting the dummy variable φ' as φ , we note the very important fact that the partition function is now represented in a Weyl *invariant* way *with respect to the new metric* $\hat{g}_{ab}$.

Now we are in a position to determine the value of Q . We found that the partition function is Weyl invariant. Therefore, the total central charge of the theory should be zero:

$$C_\varphi + C_M + C_{\text{ghost}} = 0, \quad (2.17)$$

where C_φ is the central charge for S_L , C_M is the central charge for S_M , which is equal to d , and C_{ghost} is the central charge for S_{ghost} , which is calculated to be -26 . We can evaluate C_φ with a standard technique of conformal field theory as

$$C_\varphi = 1 + 6\alpha' Q^2. \quad (2.18)$$

⁵Note that φ has the dimension of length, though ϕ is a dimensionless field.

Thus (2.17) and (2.18) give us

$$Q = \pm \sqrt{\frac{25-d}{6\alpha'}}. \quad (2.19)$$

We point out that our action is exactly the same as that of the “linear dilaton string” in $d+1$ dimensional spacetime. In the linear dilaton string, φ is regarded as one of the spacetime coordinates, and Q is given as a factor which appears in the dilaton term. However, from the viewpoint of Liouville theory, we do not regard φ as a real physical coordinate of spacetime. It is the parameter of the Weyl transformation and becomes the new spacetime coordinate through the quantization process. Thus, we call φ (or ϕ) the “Liouville mode” in this article.

Now we have some problems. First, the Liouville mode φ does not have a stable vacuum with the action (2.10). In Refs. [4] and [5], a cosmological constant is added to the action to obtain a stable vacuum. The Polyakov action with the (renormalized) cosmological constant μ is

$$S_M = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{g} (g^{ab} \partial_a X^\mu \partial_b X_\mu + \alpha' \mu). \quad (2.20)$$

It is natural to assume that the cosmological constant term is deformed by the quantum effect as

$$\begin{aligned} \frac{\mu}{4\pi} \int d^2\xi \sqrt{\hat{g}} e^\phi &\longmapsto \frac{\mu}{4\pi} \int d^2\xi \sqrt{\hat{g}} e^{\gamma\phi} \\ &= \frac{\mu}{4\pi} \int d^2\xi \sqrt{\hat{g}} e^{\alpha\varphi}, \end{aligned} \quad (2.21)$$

where γ is a constant indicating an anomalous dimension, and we defined α as $\alpha \equiv \frac{Q\alpha'}{q}\gamma$. To preserve the Weyl invariance of the theory, we choose α so that the cosmological constant term is Weyl invariant. This is realized if the conformal dimension of the operator $e^{\alpha\varphi}$ is 2. Namely, we demand $e^{\alpha\varphi}$ to be a (1,1)-primary operator. In complex coordinates, the holomorphic part of the energy-momentum tensor given by the action (2.10) is

$$T_{ZZ} = -\frac{1}{\alpha'} (\partial\varphi\partial\varphi - Q\partial^2\varphi), \quad (2.22)$$

and the conformal weight Δ of $e^{\alpha\varphi}$ is given by

$$\Delta = \frac{\alpha'}{2} \alpha \left(Q - \frac{\alpha}{2} \right), \quad (2.23)$$

which should be 1. Thus we obtain two solutions:

$$\alpha_\pm = Q \pm \sqrt{Q^2 - \frac{4}{\alpha'}} = \sqrt{\frac{25-d}{6\alpha'}} \pm \sqrt{\frac{1-d}{6\alpha'}}. \quad (2.24)$$

In the classical limit ($d \rightarrow -\infty$), α should be zero, and we take the branch of α_- . Then we have a stable vacuum for a negative world-sheet curvature $\hat{R}$. This is because the potential for φ is given by

$$V(\varphi) = \frac{1}{4\pi} \int d^2\xi (Q\hat{R}\varphi + \mu e^{\alpha\varphi}), \quad (2.25)$$

and has a minimum value if the factor of φ in the first term is negative. (We have assumed a constant- φ configuration as a classical solution here.)

We have a second problem with the strings for $d > 1$. In this region, α is a complex number. Thus we have to regard $\mu e^{\alpha\varphi}$ as a tachyon vertex operator with momentum in the φ direction, rather than a cosmological constant term. Furthermore, the composite operator $e^{\alpha\varphi}$ becomes non-normalizable [7]. We also have to consider the condensation of the target-space tachyons, since we treat a noncritical bosonic string in which the tachyonic mode is not projected out. We point out that we do not have target-space tachyons if $d \leq 1$. This is because the Liouville theory is described as a $d + 1$ -dimensional string theory, and the world-sheet oscillation can be fixed completely by the gauge symmetry if $d + 1 \leq 2$. Thus the tachyonic mode cannot appear.

For this reason, we can construct a Weyl invariant string theory with a cosmological constant for the case $d \leq 1$. A consistent model for quantized noncritical strings for $d > 1$ has not yet been constructed.

2.2 Liouville theory with boundaries

For noncritical strings with a boundary, we assume S_L to be

$$S_L = \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \{ \hat{g}^{ab} \partial_a \varphi \partial_b \varphi + \alpha' Q \hat{R} \varphi \} + \frac{1}{2\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' Q \hat{k} \varphi, \quad (2.26)$$

where s is a parameter of the boundary $\partial\mathcal{M}$ and $ds\sqrt{\hat{g}_{ss}}$ denotes an invariant infinitesimal length on it [3]. The quantity $\hat{k}$ is the extrinsic curvature with respect to the metric $\hat{g}_{ab}$. If the world-sheet has many boundaries, $\partial\mathcal{M}$ denotes all of them. The only difference between this and the boundaryless case is the existence of the boundary terms. We can also add a boundary cosmological constant term,

$$\mu_b \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} e^{\frac{\alpha}{2}\varphi}. \quad (2.27)$$

For strings with boundaries, we also need to consider the boundary conditions. We can

consider several types of boundary conditions for φ .⁶ Now we set $\hat{k} = 0$ for simplicity. The reason why this choice is natural is discussed in §3.1. In this case, we have two choices for the boundary conditions. One of them is Neumann boundary conditions, and the other is Dirichlet boundary conditions.

Neumann boundary conditions allow the ends of open strings to move freely. In other words, Neumann boundary conditions can be regarded as an equation of motion for the endpoint. Therefore, it does not restrict the discussion in §2.1, and the argument given for the boundaryless case still holds. On the other hand, we have to be careful if we consider Dirichlet boundary conditions. This is because the shift of φ (2.15) is not consistent with Dirichlet boundary conditions, and thus Weyl invariance is broken, [9] in general.

However, we show in §3.3 that we can use Dirichlet boundary conditions without breaking Weyl invariance in some special case.

3 Liouville theory as QCD string — — A trial to go beyond the $d = 1$ barrier

3.1 Liouville theory as a QCD string

We presented our basic assumptions for noncritical QCD strings in §1. Here we make these more precise before proceeding with a further argument.

The boundaries of the world-sheet correspond to non-dynamical rigid Wilson loops. In this sense, the boundary conditions for X^μ should be Dirichlet boundary conditions. A nontrivial problem is how to choose the boundary conditions for φ .

We choose the topology of the classical world-sheet to be a cylinder, and we set $\hat{k} = 0$ for simplicity. This is reasonable for the calculation of the static quark-antiquark potential. We usually consider a rectangular Wilson loop of infinite length along the time direction to calculate it. However, $\hat{k}$ diverges at the corners of the rectangle, and this makes calculations difficult. To avoid this, we connect the shorter sides (the space-like sides) of the rectangle and thereby make it periodic, like a ring. This configuration consists of two parallel circular Wilson loops, and is like a cylinder. Then, the corners disappear, and the boundaries are straight from the two-dimensional viewpoint on the world-sheet. Then we can set $\hat{k} = 0$ naturally on the world-sheet. Of course, the color charges on the loops are set to make a

⁶Boundary conditions and boundary states for linear dilaton theory have been considered by several authors. (For example, see Refs. [3],[8],[9] and references therein.)

color singlet. In the last step of the calculation, the periodicity of the loops is set to infinity, and thus the calculated value of the potential should attain the same value as that for an infinitely long rectangular Wilson loop.

Next, we make our problems clear. To go beyond the $d = 1$ barrier, we have mainly two problems to solve. First, we must stabilize the vacuum of the field φ , or fix the zero mode of φ to stabilize the classical configuration of the string. Second, we have to treat the condensation of the target space tachyons if they exist.

We propose some basic ideas to solve these problems in the following sections. We find that Dirichlet boundary conditions play important roles in the generalized Liouville theory.

3.2 Generalization of Liouville theory

We saw that the cosmological constant term becomes tachyonic for $d > 1$. Thus we cannot use it to stabilize φ .

One idea to stabilize φ without a cosmological constant is to add another Weyl invariant term to the action, which generates the minimum of $V(\varphi)$. We point out that one of the simplest candidates for such a term is

$$\frac{\mu'}{4\pi\alpha'} \int d^2\xi e^{2Q\varphi} \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu, \quad (3.1)$$

where μ' in (3.1) is a constant. This is because one can verify that the operator

$$e^{2Q\varphi} \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu \quad (3.2)$$

has conformal dimension 2, namely $\Delta(e^{2Q\varphi}) = 0$ from (2.23). Then we obtain a new action with (3.1):

$$S = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{\hat{g}} \{ (1 + \mu' e^{2Q\varphi}) \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu + \hat{g}^{ab} \partial_a \varphi \partial_b \varphi + \alpha' Q \hat{R} \varphi \} + S_{\text{ghost}}. \quad (3.3)$$

However, one finds that the above action is not exactly Weyl invariant.⁷

Let us consider the most general action for Liouville theory. We naturally impose $SO(d)$ symmetry on d -dimensional spacetime, and we then obtain

$$S = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{\hat{g}} \{ a^2(\varphi) (\partial X^\mu)^2 + (\partial\varphi)^2 + \alpha' R^{(2)} \Phi(\varphi) \}, \quad (3.4)$$

⁷Although the composite operator (3.2) is a (1,1)primary operator, multiple insertion of them creates another divergence, which causes breakdown of the scale invariance. Thus the insertion of the operator (3.2) into the action breaks Weyl invariance.

In the case of a cosmological constant term, the multiple insertions do not give any divergence.

where we have fixed the $\varphi\varphi$ -component of the target-space metric to be 1, with appropriate redefinition (or target space general coordinate transformation) of φ . Now the cosmological constant term is assumed to be zero. (We have suppressed the ghost term here. Also, note that we have dropped the boundary terms, since we set $\hat{k} = 0$.)

The β -functions which should vanish for Weyl invariance are

$$\beta_{MN}^G = \alpha'(\mathcal{R}_{MN} + 2\nabla_M \nabla_N \Phi) + O(\alpha'^2), \quad (3.5)$$

$$\beta^\Phi = \alpha' \left(-Q^2 - \frac{1}{2} \nabla^2 \Phi + (\nabla \Phi)^2 \right) + O(\alpha'^2), \quad (3.6)$$

where M and N run from 1 to $d+1$, and $X^{d+1} = \varphi$. $\mathcal{R}_{MN}$ is the Ricci tensor of the $d+1$ -dimensional target space.

Collecting the above results, the equation of motion up to order α'^2 become

$$0 = \mathcal{R}_{MN} + 2\nabla_M \nabla_N \Phi, \quad (3.7)$$

$$0 = -Q^2 - \frac{1}{2} \nabla^2 \Phi + (\nabla \Phi)^2, \quad (3.8)$$

where Q is given by (2.19). We stress that we can use these equations only in the region $\alpha' \mathcal{R} \ll 1$, where the perturbative approximation for the β -functions is valid.

The solution of these equations is given in Ref. [10] as

$$a(\varphi) = a_0 \sqrt{\frac{1 + \lambda e^{2Q\varphi}}{1 - \lambda e^{2Q\varphi}}}, \quad (3.9)$$

where λ and a_0 are constants, and

$$\Phi = Q\varphi - \frac{3}{2} \log(1 - \lambda e^{2Q\varphi}) + \frac{1}{2} \log(1 + \lambda e^{2Q\varphi}) + \text{constant}. \quad (3.10)$$

The allowed region for φ is given by $|\lambda e^{2Q\varphi}| < 1$, or

$$\varphi < -\frac{1}{2Q} \log |\lambda|. \quad (3.11)$$

We have to check the validity of this solution before further calculations. The target space scalar curvature for the solution (3.9) is given by

$$\begin{aligned} \mathcal{R} &= -3 \left(\frac{a'}{a} \right)^2 - 5 \frac{a''}{a} \\ &= \frac{-4Q^2 b}{(1-b^2)^2} (5b^2 + 8b + 5) \longrightarrow \begin{cases} -\infty & (\lambda > 0) \\ 0 & (\lambda = 0) \\ +\infty & (\lambda < 0) \end{cases} \text{ as } |b| \rightarrow 1, \end{aligned} \quad (3.12)$$

where $b = \lambda e^{2Q\varphi}$ and a' denotes $\frac{\partial a}{\partial \varphi}$. Therefore, the solution is valid only in the region satisfying $|b| \ll 1$, or equivalently

$$\varphi \ll -\frac{1}{2Q} \log |\lambda|, \quad (3.13)$$

if $\lambda \neq 0$. In the case $\lambda = 0$, the solution is exactly the same as the “linear dilaton string” considered for $d \leq 1$. We investigate the $\lambda \neq 0$ solution here. In the region satisfying (3.13), the solution is expanded as

$$a^2(\varphi) = a_0^2 \{1 + 2\lambda e^{2Q\varphi}\} + O(b^2), \quad (3.14)$$

$$\Phi(\varphi) = Q\varphi + 2\lambda e^{2Q\varphi} + O(b^2). \quad (3.15)$$

We find that the above solution is consistent with the proposed action given in (3.3), if we set $\mu' = 2\lambda$ and rescale X in (3.4) to $\frac{X}{a_0}$.

Although the best method is to find a solution for the exact equation of motion, this seems to be very difficult. Thus we consider the physics only in the region defined by (3.13), where the perturbation with respect to α' is valid, and we use the action

$$S = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{\hat{g}} \{ (1 + 2\lambda e^{2Q\varphi}) \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu + \hat{g}^{ab} \partial_a \varphi \partial_b \varphi + \alpha' \hat{R} (Q\varphi + 2\lambda e^{2Q\varphi}) \} + S_{\text{ghost}} \quad (3.16)$$

in this region.

3.3 Stabilization of the vacuum of φ

In this subsection, we attempt to stabilize the vacuum for φ in the action (3.16). We have two strategies. One is the standard stabilization using the minimum of the potential. However, we find that the potential in which we are interested has no minimum in some cases. The other one is to impose Dirichlet boundary conditions for φ and fix its zero mode. To use this method, we have to check the consistency of the Dirichlet boundary conditions and Weyl invariance.

3.3.1 Stabilization using the potential minimum

In the case that Dirichlet boundary conditions are not imposed, the zero mode of φ must be stabilized at the minimum point of the potential.

The vacua of X^μ are stable, and only the stabilization of φ is needed in our model. Thus, let us consider the effective action which we obtain after the path integration with respect to X^μ ,

$$S(\varphi) = \frac{1}{4\pi\alpha'} \int d^2\xi \sqrt{\hat{g}} \{ (1 + 2\lambda e^{2Q\varphi}) \langle \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu \rangle + \hat{g}^{ab} \partial_a \varphi \partial_b \varphi + \alpha' \hat{R} (Q\varphi + 2\lambda e^{2Q\varphi}) \}, \quad (3.17)$$

where $\langle \mathcal{O} \rangle$ denotes the expectation value of the operator $\mathcal{O}$ obtained by the path integration with respect to X^μ . The equation of motion with respect to the zero mode of φ is given by

$$\delta S = \delta\varphi_c \int d^2\xi \sqrt{\hat{g}} v'(\varphi_c) = 0, \quad (3.18)$$

where φ_c is the zero mode of φ , and $v(\varphi_c)$ is expressed by

$$v(\varphi_c) = \alpha' \hat{R} Q \varphi + 2\lambda e^{2Q\varphi_c} (\alpha' \hat{R} + \langle \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu \rangle). \quad (3.19)$$

The Gauss-Bonnet theorem states that

$$\int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \hat{R} = 4\pi\chi, \quad (3.20)$$

where χ is the Euler number of the world-sheet $\mathcal{M}$. It is given by $\chi = 2 - 2N_g - N_b$, where N_g is the number of the genus of $\mathcal{M}$, and N_b is the number of boundaries of $\mathcal{M}$. Then the equation of motion for φ_c is

$$4\pi\alpha' Q \chi + 4\lambda Q e^{2Q\varphi_c} (4\pi\alpha' \chi + A) = 0, \quad (3.21)$$

where

$$A = \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \langle \hat{g}^{ab} \partial_a X^\mu \partial_b X_\mu \rangle > 0. \quad (3.22)$$

Since $\lambda \neq 0$ and $Q \neq 0$, we obtain

$$e^{2Q\varphi_c} = -\frac{4\pi\alpha' \chi}{4\lambda(4\pi\alpha' \chi + A)} > 0, \quad (3.23)$$

and we immediately note that we have no solution for $\chi = 0$. We also obtain

$$v''(\varphi_c) = -8\pi\alpha' Q^2 \chi \quad (3.24)$$

from (3.19) and (3.21), and we have no stable vacuum for $\chi > 0$.

Note that the leading string diagram in our model is a cylinder, for which we have $\chi = 0$. In general, the leading term can be a disk ($\chi = 1$) or a cylinder in the calculation of the correlation functions of Wilson loops. Thus, unfortunately, we do not have a stable vacuum suitable for these $\chi \geq 0$ cases.⁸

⁸We have the same problem for $\chi \geq 0$ in DDK. However, in the calculation of string susceptibility, insertion of a δ -function into the path integral, which keeps the world-sheet area constant, allows us to obtain the correct value for $d \leq 1$.

3.3.2 The Weyl invariant Dirichlet boundary conditions and stabilization of the vacuum of φ

We have seen in our model that we cannot make a consistent potential for φ with disk and cylinder diagrams. However, if we impose Dirichlet boundary conditions and fix the zero mode φ_c , we are free of this difficulty.

The problem in this case is the compatibility of the Dirichlet boundary conditions and the Weyl invariance of the world-sheet. In a linear dilaton string, Dirichlet boundary conditions break Weyl invariance [9]. Therefore, we have to find a method to introduce Dirichlet boundary conditions into our theory without breaking Weyl invariance.

A good place to start is to recall the origin of the Weyl-invariance breaking in a general dilatonic string with Dirichlet boundary conditions. In dilatonic string theory, we usually need a freedom of field redefinition to preserve Weyl invariance. For example, we have to make a constant shift (a field redefinition) of φ , are in (2.15), to cancel the variation caused by the Weyl transformation (2.14) for $d \leq 1$. Dirichlet boundary conditions for φ forbids such a shift at the boundary, and breaks Weyl invariance. On the other hand, Dirichlet boundary conditions for X^μ do not break Weyl invariance, because no shift of X^μ is needed.

However, **we point out that we can employ Dirichlet boundary conditions for φ in a general dilatonic string if the criterion stated below is satisfied.** In the theory with a dilaton, the required shift of the field is not a constant in general. For example, the shifts we need for the fields in (3.4) at the one-loop level are given as

$$\delta\varphi = -\frac{\alpha'}{2}\partial_\varphi\Phi(\varphi)\delta\sigma, \quad (3.25)$$

$$\delta X^\mu = 0, \quad (3.26)$$

where ∂_φ stands for $\frac{\partial}{\partial\varphi}$.⁹ We can check that (3.25) gives the correct constant shift required in the linear dilaton case (2.15) if we set $q = 2$.¹⁰ We look deeper into the origin of the field redefinition in the Appendix.

We note that we do *not* need field redefinition for φ if $\partial_\varphi\Phi = 0$. Therefore, we can use the Dirichlet boundary conditions

$$\varphi|_{\partial\mathcal{M}} = \varphi_0, \quad (3.27)$$

⁹The required field redefinition to preserve Weyl invariance appears in articles which discuss the β -functions for non-linear sigma models. For the models with boundaries, see Refs. [11] and [12]. The condition (3.25) for the shift is also found in Ref. [9].

¹⁰If $q = 2$, we get $u = \frac{1}{2}\frac{d-25}{48\pi}$. The denominator naturally coincides with the denominator of the factor in (2.8). In this linear dilaton case, the Weyl anomaly is obtained exactly at the one-loop level.

where

$$\partial_\varphi \Phi(\varphi)|_{\varphi=\varphi_0} = 0, \quad (3.28)$$

without breaking Weyl invariance at the one-loop level. The above stated criterion for consistent Dirichlet boundary conditions is one of the most important assertions of this article.

As a next step, let us examine whether our model (3.16) has such a φ_0 or not. Our dilaton term is

$$\Phi(\varphi) = Q\varphi + 2\lambda e^{2Q\varphi} + O(b^2). \quad (3.29)$$

Thus the condition (3.28) is

$$\partial_\varphi \Phi = Q + 4\lambda Q e^{2Q\varphi} + O(b^2) = 0, \quad (3.30)$$

and we obtain

$$\varphi_0 = -\frac{1}{2Q} \log(-4\lambda) + O(b^2) \quad (3.31)$$

for $\lambda < 0$. The condition (3.30) is valid only in the region satisfying $|b| = |\lambda e^{2Q\varphi}| \ll 1$, and now $\lambda e^{2Q\varphi_0} = -1/4$. Thus the above result suggests that we have an appropriate point φ_0 for the Dirichlet boundary conditions (3.27) if $\lambda < 0$.

For this reason, we choose $\lambda < 0$ and impose Dirichlet boundary conditions on the ends of the string to stabilize its configuration for arbitrary χ . Note that the above argument naturally selects the branch of λ uniquely.

3.4 Tachyon condensation: another role of Dirichlet boundary conditions in Liouville theory

We found that we can use Dirichlet boundary condition to stabilize the string configuration, while preserving Weyl invariance for arbitrary χ , at least up to $O(\alpha'^2)$.

However, we have another big problem: If the target-space dimension ($d+1$ for our model) is greater than 2, we cannot fix all of the freedom of the world-sheet oscillation with gauge symmetry, and we have a physical oscillation. It is well known that we have a tachyonic state in the oscillation mode of the bosonic string in flat spacetime. In our model (3.16), the target space becomes asymptotically flat in the region $\varphi \ll 0$. Now we are considering the case $d > 1$. Thus a tachyonic ground state appears in the region in which the spacetime is almost flat. If we have a tachyonic mode, we have to handle tachyon condensation.

Tachyon condensation has been discussed by many authors (for example, see Ref. [13]), but this subject is difficult and has not yet been solved completely. We present some ideas to treat tachyon condensation here [14]. We stress that Dirichlet boundary conditions play an important role in this subsection too.

First, let us recall field condensation in usual quantum field theories. In field theory with field condensation (that is, in the theory with nonzero expectation value of the field), we can calculate correct quantities if we know the correct expectation value of the field, even with the perturbation around an incorrect vacuum. For example, we can calculate the exact propagator with the perturbation around an incorrect vacuum by attaching tadpole diagrams to the tree propagator. Even though the mass squared is negative in a description around such a vacuum, tadpoles with appropriate weight create an additional shift of the mass squared, and make the total mass squared positive. In such a case, although the tachyonic mode exists in a perturbative theory around an incorrect vacuum, the theory is never wrong, and only the “vacuum” is wrong. In field theories, the true vacuum or exact expectation value of the field can be given by the Schwinger-Dyson equation. Thus we can get the correct weight of the tadpoles, we can calculate the correct propagator, and so on.

We now make an analogy between field theories and tachyonic string theories. Although we have a tachyonic mode, we believe that the string theory is not fatally flawed, and the problem is that we do not know the true vacuum of it. The analogy with field theories tells us that we may be able to obtain correct quantities if we attach correct “tadpoles” to the world-sheet. Then, the question is what is the “tadpole” in string theories.

We guess here that the tadpole in string theories is a macroscopic hole with Dirichlet boundary conditions in the world-sheet. We assume that the Dirichlet boundary condition for them is

$$X^\mu(\xi_i) = a_i^\mu, \quad (3.32)$$

$$\varphi(\xi_i) = \varphi_0, \quad (3.33)$$

where i distinguishes each tadpole, a_i^μ is a constant, and φ_0 is a constant which satisfies the condition (3.28). Of course, we have to consider the proper weights of the string wave functions on it. The above assumption results from the following considerations.

The tachyonic tadpole is an off-shell state, because it does not carry momentum. We also know that off-shell states in string theory do not correspond to local emission vertexes.

Thus we naturally assume that the tachyonic tadpole is a non-local macroscopic hole on the world-sheet.¹¹ We also have to preserve Weyl invariance, and it is natural to impose the above Dirichlet boundary conditions (3.32) and (3.33) on the edge of the hole. Neumann boundary conditions cannot be taken for a tadpole for the following reason. If we impose Neumann boundary conditions at a hole, the value of X^μ changes along the edge of the hole. This means that we observe a macroscopic hole even in d -dimensional spacetime. Although the Neumann boundary conditions for φ do not make a macroscopic hole in the visible d -dimensional spacetime, the hole can have momentum in the φ direction. This allows us to make an on-shell state, and the hole can break into on-shell open strings moving along the φ direction. These situations do not seem to be natural for our model. Contrastingly, the tadpole with the Dirichlet boundary conditions (3.32) and (3.33) does not leak any momentum from the world-sheet, and this gives a natural property for the tadpole.

The macroscopic holes with Dirichlet boundary conditions on the world-sheet (or D-instantons in the target space) and the non-perturbative effects induced by them are discussed in Refs. [15] and [9]. However, we insist that the macroscopic holes discussed here play the role of “tadpoles” naturally even in Liouville theory.

Unfortunately, we do not have the Schwinger-Dyson equation of string theory, and we do not know how to obtain the correct weight which should be attached to the tadpole. Thus, we cannot give a rigorous discussion to treat tachyon condensation, but we present a rough argument regarding tachyon condensation.

To treat a macroscopic hole on the world-sheet is rather difficult, and we therefore approximate it as a point on the world-sheet which couples to the Dirichlet boundary conditions. In this case, the insertion of the tadpole is regarded as the insertion of

$$h \int_{\mathcal{M}} d^2\xi_1 \sqrt{\hat{g}} \delta(X^M(\xi_1) - a^M(\xi_1)) \quad (3.34)$$

into the world-sheet, where h is the weight of the tadpole, and ξ_1 denotes the insertion *point* on the world-sheet. We have $X^{d+1} = \varphi$ and $a^{d+1} = \varphi_0$. In usual strings without a dilaton, the δ -function in (3.34) becomes 1 after the integration over the moduli a^M , and the string propagator with the tadpoles can be estimated as

$$\begin{aligned} \text{propagator} &= \frac{1}{L_0 + \bar{L}_0} + \frac{1}{L_0 + \bar{L}_0} h \frac{1}{L_0 + \bar{L}_0} + \frac{1}{L_0 + \bar{L}_0} h \frac{1}{L_0 + \bar{L}_0} h \frac{1}{L_0 + \bar{L}_0} + \cdots \\ &= \frac{1}{L_0 + \bar{L}_0 - h}, \end{aligned} \quad (3.35)$$

¹¹Some argument for the macroscopic hole as a tachyonic state is given in Ref. [7].

where L_0 ($\bar{L}_0$) is the (anti)holomorphic part of the Hamiltonian of the corresponding conformal field theory. Thus, the insertion of the tadpoles (3.34) seems to make an additional shift to the energy of the tachyonic state.

However, we cannot apply the above estimation directly to Liouville theory. Although we should integrate over a^μ to get Poincaré invariance in the d -dimensional spacetime, we never integrate over φ_0 in our model (because it is fixed). Therefore, the expected non-perturbative effects induced by the tadpoles in Liouville theory seem to be different from those of non-dilatonic strings. In any case, we must develop a technique to estimate the effects of the insertion of Dirichlet boundaries.

4 Conclusion

We attempted to quantize a noncritical (four dimensional) bosonic string as a natural candidate of a (large- N) pure QCD string. We considered the generalized Liouville action (3.4) as such a string.

One of the main problems here is the stabilization of the Liouville mode φ while preserving Weyl invariance, and we found that we can stabilize it with the Dirichlet boundary conditions (3.27). The criterion for consistent Dirichlet boundary conditions at the one-loop level is given by (3.28), and the stabilized point is independent of the topology of the world-sheet. We found that the perturbative solution for the background in (3.4) seems to have a point which satisfies the condition (3.28). This argument led us to the unique selection of the branch of the solution.

We also discussed tachyon condensation. Although the complete treatment of it is very difficult, we presented a simple strategy for it. The idea we presented is to attach tadpoles to the world-sheet, and we guessed that the tadpole in string theories might be represented as a macroscopic hole with Dirichlet boundary conditions. In non-dilatonic cases, a naive approximation for the propagator with tadpoles implies a shift of the energy of the tachyonic state. However, we guess that the non-perturbative effects in Liouville theory are different from those of non-dilatonic strings.

Before we close this article, we stress again that Dirichlet boundary conditions have an important role in the generalized Liouville theory, and they can be imposed on the Liouville mode while preserving Weyl invariance if the appropriate condition mentioned above is satisfied. The investigation of Dirichlet strings in dilatonic backgrounds is very important,

and it should yield necessary information about the construction of noncritical strings.

Acknowledgments

The author would like to thank Professor H.Kawai for valuable and inspiring discussion about the subjects presented here.

A The Origin of the Field Redefinition and the Derivation of (3.25)

Here we look deeper into the origin of the necessity of the field redefinition, at the one-loop level [namely, up to $O(\alpha'^2)$]. Let us consider a general string action in $d + 1$ dimensions,

$$S = \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \{ G_{MN}(\mathbf{X}) \hat{g}^{ab} \partial_a X^M \partial_b X^N + \alpha' \hat{R} \Phi(\mathbf{X}) \} + \frac{1}{2\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' \hat{k} \Phi(\mathbf{X}(s)), \quad (\text{A.1})$$

where we have included the boundary term, as it is needed in following calculation.¹² The renormalized action with dimensional regularization up to two loops is expressed as

$$S = \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^{2+\epsilon}\xi \sqrt{\hat{g}} \left(G_{MN}(\mathbf{X}) + \alpha' \frac{1}{\epsilon} C_{MN}(\mathbf{X}) \right) \hat{g}^{ab} \partial_a X^M \partial_b X^N + \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^{2+\epsilon}\xi \sqrt{\hat{g}} \alpha' \hat{R} \left(\Phi(\mathbf{X}) + \frac{1}{\epsilon} C_{\Phi}(\mathbf{X}) \right) + \frac{1}{2\pi\alpha'} \int_{\partial\mathcal{M}} d^{1+\epsilon}s \sqrt{\hat{g}_{ss}} \alpha' \hat{k} \left(\Phi(\mathbf{X}(s)) + \frac{1}{\epsilon} \tilde{C}_{\Phi}(\mathbf{X}(s)) \right), \quad (\text{A.2})$$

where the symmetric tensor $\frac{1}{\epsilon} C_{MN}$ is the counterterm of the kinetic term, and the scalar $\frac{1}{\epsilon} C_{\Phi}$ ($\frac{1}{\epsilon} \tilde{C}_{\Phi}$) is the counterterm of the dilaton term in $\mathcal{M}$ ($\partial\mathcal{M}$).¹³ If we perform the Weyl transformation $\hat{g}_{ab} \mapsto \hat{g}_{ab} e^{\delta\sigma}$ and take the limit of $\epsilon \rightarrow 0$, the finite variation of the action at $O(\delta\sigma)$ is

$$\delta_{\sigma} S = \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \alpha' \left\{ \frac{1}{2} \delta\sigma C_{MN}(\mathbf{X}) \hat{g}^{ab} \partial_a X^M \partial_b X^N + \hat{R} \frac{1}{2} \delta\sigma C_{\Phi}(\mathbf{X}) \right\} - \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \alpha' (\Phi(\mathbf{X}) + C_{\Phi}(\mathbf{X})) \nabla^2(\delta\sigma) + \frac{1}{2\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' \hat{k} \frac{1}{2} \delta\sigma \tilde{C}_{\Phi}(\mathbf{X}(s)) + \frac{1}{2\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' \frac{1}{2} (\hat{n}^a \partial_a(\delta\sigma)) (\Phi(\mathbf{X}(s)) + \tilde{C}_{\Phi}(\mathbf{X}(s))), \quad (\text{A.3})$$

¹²For the non-linear sigma model with boundaries, see Refs. [11] and [12].

¹³We implicitly renormalized quadratically divergent terms into the cosmological constant term, and we set them to zero.

where $\hat{n}^a$ is the unit outward normal vector. The term which contains $\nabla^2(\delta\sigma)$ in (A.3) is rewritten as

$$\begin{aligned}
& - \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \hat{g}^{ab} \alpha' \left\{ \nabla_a \nabla_b X^M \nabla_M (\Phi(\mathbf{X}) + C_\Phi(\mathbf{X})) \right. \\
& \quad \left. + \partial_a X^M \partial_b X^N \nabla_M \nabla_N \Phi(\mathbf{X}) \right\} \delta\sigma \\
& - \frac{1}{4\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' (\hat{n}^a \partial_a (\delta\sigma)) (\Phi(\mathbf{X}(s)) + C_\Phi(\mathbf{X}(s))) \\
& + \frac{1}{4\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \alpha' \hat{n}^a \partial_a X^M \nabla_M (\Phi(\mathbf{X}(s)) + C_\Phi(\mathbf{X}(s))) \delta\sigma, \tag{A.4}
\end{aligned}$$

where M and N are the indices of the coordinates of spacetime, and ∂_N stands for $\frac{\partial}{\partial X^N}$.

Therefore we get

$$\begin{aligned}
\delta_\sigma S &= \frac{1}{4\pi} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \left\{ \left(\frac{1}{2} C_{MN}(\mathbf{X}) - \nabla_M \nabla_N \Phi(\mathbf{X}) \right) \hat{g}^{ab} \partial_a X^M \partial_b X^N \right. \\
& \quad \left. + \hat{R} \frac{1}{2} C_\Phi(\mathbf{X}) \right\} \delta\sigma \\
& + \frac{1}{2\pi} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \hat{k} \frac{1}{2} \tilde{C}_\Phi(\mathbf{X}(s)) \delta\sigma \\
& + \frac{1}{4\pi} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} (\hat{n}^a \partial_a (\delta\sigma)) (\tilde{C}_\Phi(\mathbf{X}(s)) - C_\Phi(\mathbf{X}(s))) \\
& - \frac{1}{4\pi} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} \hat{g}^{ab} \nabla_a \nabla_b X^M \nabla_M (\Phi(\mathbf{X}) + C_\Phi(\mathbf{X})) \delta\sigma \\
& + \frac{1}{4\pi} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} \hat{n}^a \partial_a X^M \nabla_M (\Phi(\mathbf{X}(s)) + C_\Phi(\mathbf{X}(s))) \delta\sigma. \tag{A.5}
\end{aligned}$$

The last three terms cannot be absorbed into any counterterm. The third term of (A.5) goes to zero if $\tilde{C}_\Phi = C_\Phi$. This is realized if all the β -functions, except for that of the dilaton, vanish [12]. The problem is to determine how to deal with the last two terms.

Fortunately, we can cancel them using field redefinition. If we perform a field redefinition $X^M \mapsto X^M + \delta X^M$, the variation of the action is

$$\begin{aligned}
\delta_X S &= \frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} 2\hat{g}^{ab} \partial_a X^M \partial_b \delta X_M \\
& + (\text{terms proportional to } \delta X_M) \\
& = -\frac{1}{4\pi\alpha'} \int_{\mathcal{M}} d^2\xi \sqrt{\hat{g}} 2\hat{g}^{ab} \nabla_a \nabla_b X^M \delta X_M \\
& + \frac{1}{4\pi\alpha'} \int_{\partial\mathcal{M}} ds \sqrt{\hat{g}_{ss}} 2\hat{n}^a \partial_a X^M \delta X_M \\
& + (\text{terms proportional to } \delta X_M). \tag{A.6}
\end{aligned}$$

Therefore, if we set

$$\delta X^M = -\frac{\alpha'}{2} \nabla^M (\Phi(\mathbf{X}) + C_\Phi(\mathbf{X})) \delta\sigma, \tag{A.7}$$

we can cancel the last two terms of (A.5). The remaining terms proportional to δX_M in (A.6) can be absorbed into the counterterms. Thus, after a proper field redefinition, $\delta_\sigma S + \delta_X S$ contains only terms proportional to the β -functions, and we can preserve Weyl invariance if we set each of the β -functions to zero. We know that the counterterm C_Φ at the one-loop level corresponds to the central charge, and is a constant. Thus the required shift of X^M is

$$\delta X^M = -\frac{\alpha'}{2} \nabla^M \Phi(\mathbf{X}) \delta \sigma. \quad (\text{A.8})$$

Now we emphasize the very important fact that we do *not* need field redefinition at the special point $\mathbf{X}_0$ where $\nabla^M \Phi(\mathbf{X}_0) = 0$.

In our model (3.16), G_{MN} , Φ and the counter terms depend only on $X^{d+1} = \varphi$, so that (A.8) can be written as

$$\delta \varphi = -\frac{\alpha'}{2} \nabla^\varphi \Phi(\varphi) \delta \sigma \quad (\text{A.9})$$

$$\delta X^\mu = 0, \quad (\text{A.10})$$

where μ runs from 1 to d and $\nabla^\varphi = \nabla^{d+1}$. Now $G^{\varphi\varphi} = 1$, and $\nabla^\varphi \Phi = \nabla_\varphi \Phi$. Thus we obtain (3.25).
